Key Points.

  ○ Lateral detrainment clearly observed from North Wall at depth.

  ○ Salt flux similar to bulk estimates.

  ○ Detrained water is from a distinct partially mixed water class.

3 The Gulf Stream is a major conduit of warm surface water from the trop-

4 ics to the subpolar North Atlantic. Here we observe and simulate a sub-mesoscale

5 (< 20 km) mechanism by which the Gulf Stream exchanges water with sub-

6 polar water to the north. The front exhibits a sharp temperature-salinity con-

7 trast, with distinct "mixed" water between the two water masses 2 and 4 km

8 wide. This mixed water does not increase downstream despite substantial

9 energy available for mixing. A series of "streamers" detrain this water at the

10 crest of meanders. Subpolar water replaces the mixed water and resharpens

11 the front. The water mass exchange accounts for a northwards flux of salt

12 of $0.8 - 5$ psu m^{2}s^{-1}, (large-scale diffusivity $O(100$ m^{2}s$^{-1}))$. This is sim-

13 ilar to bulk-scale flux estimates of 1.2 psu m^{2}s^{-1}, and supplies fresh water

14 to the Gulf Stream required for the production of 18-degree subtropical mode

15 water.

1. Introduction

16   The Gulf Stream (GS) is the western boundary current of the North Atlantic subtropical

17   wind-driven circulation. It separates from Cape Hatteras where it flows eastward into the

18   North Atlantic. As it flows, it loses heat to the atmosphere and by mixing with the cold

19   water in the subpolar gyre to the north. It also becomes fresher, an observation that can

20   only be explained by entrainment of fresh water from the north [*Joyce et al.*, 2013]. As it

21   entrains water, the GS increases its eastward transport by approximately $40 - 80$ m^{2}s^{-1}

22   [*Johns et al.*, 1995].

23   The GS has a sharp density front that outcrops at the surface. It also has a sharp

24   temperature and salinity front, as has been demonstrated at the surface from shipboard

25   surveys [*Ford et al.*, 1952] and satellite images [*Churchill et al.*, 1989]. The sharpness of the

26   front beneath the surface has been less-clear, and requires high-resolution lateral sampling

27   to resolve. The front has a sharp potential vorticity gradient [*Rajamony et al.*, 2001], and

28   such gradients act as a barrier to lateral mixing [*Marshall et al.*, 2006; *Naveira Garabato*

29   *et al.*, 2011]. Despite this barrier, property budgets indicate that there is significant

30   exchange across the north wall [*Joyce et al.*, 2013], and that entrainment of fresh water

31   is necessary to create the dynamically important "18-degree water" that fills much of the

32   upper Sargasso Sea.

33   The mechanisms controlling this lateral mixing have not been identified. There are large

34   eddies that periodically pinch off the GS and carry warm water to the north. However,

35   some of these are re-entrained into the GS and do not result in a net exchange. Instead,

36   tracer budgets across the front appear to be dominated by small, submesoscale processes

[*Bower et al.*, 1985]. To date some of the best direct evidence for cross-front exchange consists of the trajectories of density-following floats placed at the north wall [*Bower and Rossby*, 1989; *Bower and Lozier*, 1994]. These floats were observed to regularly detrain from the GS, such that of 95 floats, 26 stayed in the GS, 7 were detrained in rings, and 62 were detrained by mechanisms other than rings [*Bower and Lozier*, 1994]. Kinematic theories have been examined to explain the detrainment of the floats [*Flierl et al.*, 1987; *Stern*, 1985; *Pratt et al.*, 1995], and the similarity to satellite images of "streamers" of warm water detraining from the Gulf Stream has been noted. However, direct observations of the processes as it occurs at depth have been lacking.

Here we point out that the density front is accompanied by a sharp (¡5 km wide) and persistent temperature-salinty front along isopycnals. We also present indirect evidence that there is small-scale mixing (<0.5 km) on the northern cyclonic side of the GS, and that the mixed water periodically peels off the GS in thin (5-10 km wide) "streamers". We describe our experiment, and the observations that it yielded before briefly discussing the implications.

2. Methods

In March 2012 we made high-resolution measurements of the north wall of the GS from 66 W to 60 W (figure 1), about 850 km east of where the GS separates from the North American continental slope. A Lagrangian float [*D'Asaro*, 2003] was placed in the Gulf Stream front based on a brief cross-stream survey, and programmed to match the density of the surface mixed layer (upper 30 m). The float moved downstream at a mean speed of $1.4 \, \mathrm{m \, s^{-1}}$. The *R/V Knorr* tracked the float and deployed a Chelsea Instruments TriAxus

that collected temperature, salinity, and pressure (CTD) on a 200-m deep sawtooth with

approximately 1-km lateral spacing in a 10-km box-shaped pattern relative to the float

(figure 1, magenta). *R/V Atlantis* performed larger cross sections approximately 30 km

across the front, trying to intercept the float on each front crossing. *R/V Atlantis* was

deploying a Rolls Royce Marine Moving Vessel Profiler equipped with a CTD that profiled

to 200 m approximately every 1 km. Both ships had a 300 kHz RDI Acoustic Doppler

Current Profiler (ADCP) collecting currents on 2-m vertical scale averaged every 5 minutes

(approximately 1 km lateral scale), collected and processed using UHDAS and CODAS

(http://currents.soest.hawaii.edu *Firing et al.* [2012]). Velocities are put into a float-

following frame as a proxy for along- and across-front, with u being defined as along the

floats path, and v as perpendicular to the path and to the north. Velocity data at 2-m

vertical resolution reached about 130 m, and were supplemented at deeper depths with

data from 75 kHz RDI ADCPs, with 8-m vertical resolution.

Data were interpolated onto a cube delineated by depth surfaces by creating a two-

dimensional interpolation onto a grid via Delauney triangulation at each depth; no ex-

trapolation was performed. Data on the 26.25 $\mathrm{kg\,m^{-3}}$ isopycnal were assembled at each

grid point by finding the first occurrence of that isopycnal in depth. Potential vorticity is

calculated from the three-dimensional grid as

$$q = -\frac{g}{\rho_0}\left(\nabla \times \mathbf{u} + \mathbf{f}\right) \cdot \nabla\rho, \tag{1}$$

where f is the Coriolis frequency, g the gravitational acceleration. The bracketed term

is twice the angular velocity, including the planet's rotation, and the gradient of density

represents the stretching or compression of the water column. In the GS, the poten-

tial vorticity is dominated by contributions from the vertical density gradient and the cross-stream gradient of the along-stream velocity, which was used to calculate potential vorticity from two-dimensional sections:

$$q \approx N^2 \left(-\frac{\partial u}{\partial y} + f \right). \tag{2}$$

At select times during the float evolutions, fluorescein dye releases (100 kg per release) were conducted at depth as close as possible to the float. Dye was pumped down a hose to a tow package deployed off the side of the ship, consisting of a CTD and a dye diffuser. Prior to injection, the dye was mixed with alcohol and ambient sea water to bring it to within 0.001 kgm^{-3} of the float's target density. Initial dimensions of the dye streak were $\approx$1 km along-stream, $\approx$100 m cross-stream (after wake adjustment), and ranging from 1 - 5 m in the vertical. The TriAxus system on the *R/V Knorr* tracked the fluorescein from its CTD package.

Numerical simulations of the GS were performed with the Regional Oceanic Modeling System [ROMS *Shchepetkin and McWilliams*, 2005]. The simulation has a horizontal resolution of 500m and 50 vertical levels. The model domain spans 1,000 km by 800 km and covers a region of the GS downstream from its separation from the U.S. continental slope. Boundary conditions are supplied by a sequence of two lower-resolution simulations that span the entire GS region and the Atlantic basin, respectively. The simulation is forced by daily winds and diurnally modulated surface fluxes. The modelling approach is described in detail in *Gula et al.* [2015].

Neutrally buoyant Lagrangian (flow-following) particles were seeded into the model at a time $t0$ and advected both backwards and forwards in time by the model velocity fields

89 without additional dispersion from the model's mixing processes [*Gula et al.*, 2014]. A

90 4th-order Runge-Kutta method with a time step $dt = 1$ s is used to compute particle

91 advection. Velocity and tracer fields are interpolated at the positions of the particles

92 using cubic spline interpolation in both the horizontal and vertical directions. We use

93 hourly outputs from the simulation to get sufficiently frequent and temporally-smooth

94 velocity sampling for accurate parcel advection.

3. Observations

95 During these observations, the GS had a shallow meander crest at 65 W (figure 1b)

96 followed by a long concave region (63 W) and then another large crest (61 W). Satellite

97 measurements show the sharp temperature changes across the front, superimposed with

98 thin intermediate-temperature (15-18°C) streamers detraining to the north at approxi-

99 mately 65 W, 64 W, and at the crest of the large meander at 61 W. An older streamer

100 that has rolled up can also be seen at 62 W. The ships passed through the three newer

101 streamers providing a detailed observation of their underwater structure.

102 The front consists of density surfaces that slope up towards the north (figure 2a-d).

103 The water along density surfaces is saltier (and warmer) in the GS, and fresher (and

104 colder) to the north. The transition between the two water masses is remarkably abrupt,

105 occurring over less than 5-km. This sharpness persisted from the western-most section

106 during the cruise (71.5 W) to the eastern-most (60.5 W). Some cross sections show lateral

107 interleaving of salinity north of the front deeper than 70 m (figure 2a) with approximately

108 5-km wide salinity anomalies ($S \approx 36.15$ psu). These anomalies move slower than the

109 front (figure 2e), and have high potential vorticity that is normally associated with the

110 front (figure 2i). The surface signature of the streamers (as seen in figure 1b) can be

111 also seen in these cross-sections as saltier "surface" water (figure 2a-d)), but the T/S

112 characteristics are not as distinct because of cooling by the atmosphere.

113   The temperature-salinity (T/S) relationship of this data shows the contrast between the

114 GS and the subpolar water as two distinct modes (figure 3, labeled "North" and "Gulf

115 Stream"), except near the surface where the water masses are strongly affected by the

116 atmosphere. For the deeper water, there is a third distinct population between the two

117 larger modes in T/S space that represents the water in the salinity anomalies, that we

118 have labelled as "streamers". The distinctness in T/S space of the streamers indicates

119 that after the GS and subpolar waters mixed, the partially mixed water continued to mix,

120 condensing it in T/S space so that it forms an almost-separate water mass. Below, we

121 further differentiate water in this T/S class as either "attached" to the GS or "detached".

122   Looking at the GS in plan view along the $\sigma_\theta = 26.25 \mathrm{~kg~m}^{-3}$ isopycnal (figure 4a) we

123 see the mixed water that that makes up the streamers is connected along the length of

124 our observations, with a width that averages just less than 4km wide (figure 4b). The first

125 streamer (64.5 W) is horizontally connected over 100 km, and is about 5 km wide, and

126 at least 150 m deep. Where the streamer is the most detached (figure 2a) the main front

127 is the sharpest of the four cross sections. Downstream of this streamer, the mixed water

128 thins before the eastern meander (60.5 W) where there is a second streamer. Further

129 downstream, the mixed water almost disappears by the last cross-section (59 W), and

130 there is evidence of a streamer to the north of the sampling pattern.

131   We can estimate the rate of detrainment from the first streamer (64.5 W). It starts

132   on the fast side of the front with water flowing approximately $0.1 - 0.25$ m s^{-1} faster

133   than the float (figure 2h). Upstream, where it is detached (figure 2e), it is flowing almost

134    $0.2 - 0.5$ m s^{-1} slower than the float. Integrating the transport relative to the attached

135   water just downstream, we see that the streamer detrains $0.2 - 0.25 \times 10^6$ m^3 s^{-1} of water

136   (figure 4c). This estimate is quite rough, given that the fully detached streamer was only

137   sampled three times, the arbitrary division between "attached" and "detached" water,

138   and the overall inhomogeneity of the water mass, but it serves as a rough estimate until

139   better measurements can be made.

140   The streamers move up through the water column along isopycnals and the water parcels

141   are stretched vertically. The streamer in figure 2a has risen along isopycnals from 140 m

142   deep (figure 2d) to less than 40 m deep (figure 2a), and titled somewhat as it has done so.

143   The velocity anomaly is about 0.75 m s^{-1} over 100 km so we estimate that the streamer

144   is approximately 1.5 days old, implying vertical velocities of order 50 m/day, similar to

145   rates inferred from large-scale omega-equation calculations [*Thomas and Joyce*, 2010].

146   Concurrently, there is a bolus of fresh water from the north that is enfolded between

147   the streamers and the GS that we will call an "intrusion". This entrained water is part of

148   the strong shear on the North Wall, so the amount of entrainment is harder to quantify

149   than the detrainment from these observations.

150   A different survey (14 Mar) included a dye release in water that was subsequently

151   entrained between the wall and a streamer (figure 5a-c). The dye was injected near the

152   surface at the North Wall, centered at approximately 50 m depth on the 26.0 kg m^{-3}

isopycnal in the fresh water. A subsequent pass 43 km downstream shows that the dye

has been enfolded in a streamer (figure 5b). In T/S space, this water is in the "surface"

water class (figure 5c). This particular streamer did become deeper, down to 100 m, and

deterained further from the front than shown here.

4. Simulations

High-resolution numerical simulations ($dx \approx 500m$, see methods) resolve these features

and also confirm the entrainment of the fresh intrusion (figure 5d-i). Seeding the sim-

ulation with Lagrangian particles (see methods) allows us to track the evolution of the

streamers and the intrusion as the flow moves downstream. Before the streamer is formed,

the water in the intrusion (magenta contours) is near the surface and the streamer water

(green contours) is well within the front (figure 5d,g). Downstream (figure 5e,h) the fresh

water has been subducted to 150 m depth, and the streamer has been pushed north of

the front. Both water masses accelerate with the GS (figure 5f), but the fresh intrusion

accelerates more, such that the intrusion is entrained and the streamer slows and is de-

trained. As in the observations, the streamer occupies an intermediate region in T-S space

(figure 5i, green contour), and originates in the high-vorticity region of the front. The

acceleration of the fresh intrusion relative to the streamer is an important finding of the

model, as the fresh water now forms a new sharp T-S front with the warm salty GS, and

the mixed streamer water is carried away from the front. The model further shows that

the streamers are more prominent on the leading edges of meanders, also clearly seen in

satellite images (figure 1).

173   There are differences with the observations, however. The data show very distinct T-S

174   signatures associated with the streamers, whereas the model streamer T/S "mode" is less

175   isolated (figure 5i). The two interleaving water masses are confined to a narrow isopycnal

176   band in the model, with the intrusion being slightly lighter than the streamer, whereas

177   in the observations the temperature-salinity front cuts across more isopycnals (compare

178   figure 2b to figure 5h). There is also clear evidence of strong subduction of the intrusion

179   in the model, reminiscent of intrathermocline eddies *Thomas and Joyce* [2010]. Overall,

180   the model has similar dynamics, but likely lacks sub-km mixing processes that create the

181   "streamer" water in exactly the way it is created in nature.

5. Discussion

182   The distinct T/S mode on the density-compensated front of the Gulf Stream is a new

183   finding to our knowledge, and enabled by our very high density of sampling. The impli-

184   cation of this water class is that mixing at the Gulf Stream front is relatively "complete"

185   in that water trapped in an instability is trapped there for long enough that it is homog-

186   enized. Symmetric instability is believed to be quite "explosive" and this T/S mode may

187   be indirect evidence for its role at the North Wall[*D'Asaro et al.*, 2011].

188   The streamers that detrain from the north wall have been seen in satellites and inferred

189   from floats [*Bower and Rossby*, 1989; *Flierl et al.*, 1987; *Lozier et al.*, 1997; *Song et al.*,

190   1995], however this is the first time they have been shown to penetrate so deep and to

191   be composed primarily of the mixed class of water. The detrainment helps explain why

192   the front at the north wall of the GS remains so sharp. That only the mixed water

193   is carried away, and not high-salinity GS water (figure 4a) is a mystery. This implies

194 a dynamical link that we have not seen explored. Kinematic models have been made

195 of streamers in which particles are displaced from streamlines going around propagating

196 meanders [*Bower*, 1991; *Pratt et al.*, 1995; *Lozier et al.*, 1997]. The observations here

197 add to these models by showing that it is only mixed water that leaves the GS. This

198 co-incidence indicates to us a role for small-scale mixing in producing the destabilizing

199 forces that cause this water to detrain from the north wall.

200 The streamers appear to be one of the processes that balance large-scale budgets of

201 exchange across the GS [*Joyce et al.*, 2013; *Bower et al.*, 1985]. Such budgets sug-

202 gest that this region of the GS loses salinity to the north at a rate of 1.2 psu m^{2}s^{-1}

203 [*Joyce et al.*, 2013]. If each streamer transports $0.2 - 0.25 \times 10^6$ m^{3}s^{-1} of water that

204 is $0.8 - 1$ psu saltier than the water that is entrained, and streamers appear approxi-

205 mately every 100-300 km, associated with meanders, then an estimate of their average

206 transport is $0.5 - 2.5$ psu m^{2}s^{-1}, bracketing the large-scale estimates. Working against a

207 gradient of 1 psu/10 km over 200 m depth, the equivalent mesoscale lateral diffusivity is

208 $25 - 125$ m^{2}s^{-1}. These estimates are approximate, and based on one observation of one

209 streamer. Presumably some streamers are stronger than others, and better statistics are

210 desirable. Similarly, whether the streamers are the rate-limiting mechanism driving salt

211 flux out of the GS, as opposed to the small-scale turbulence at the wall, is unknown.

212 Here we have observed a submesoscale lateral stirring process along the north wall of the

213 GS. The T/S front remains persistently sharp, despite small-scale mixing evident from the

214 T/S diagrams, and due to a number of possible processes [*Thomas and Shakespeare*, 2015;

215 *Whitt and Thomas*, 2013]. The mixed water mass does not accumulate, or it would weaken

216 the sharpness of the front. Here we show that the streamers detrain mixed water, and

217 entrain cold and fresh water toward the north wall, resharpening the temperature-salinity

218 front. Further analysis of the data and models will shed light on the exact mechanism

219 triggering the ejection of water from the front via the streamers.

Figure 1: The experimental design Inset: The experiment site on the north wall of the Gulf Stream, between 66 and 60 W, as shown in an AVHRR satellite image of sea surface temperature (SST). Main: Detailed SST image composed from two satellite images. The GS is warm and delineated by a sharp front. The small sub-mesoscale structures north of the front are the focus of this paper. The satellite images are a composite from early in the observation period (AVHRR 6 Mar), and late (MODIS, 9 Mar). A Lagrangian float was deployed in the front (black curve), and the ship tracks bracketed the float's position (green: *R/V Atlantis*, magenta: *R/V Knorr*). *R/V Atlantis* cross-sections labeled a-d are shown in figure 2a-d.
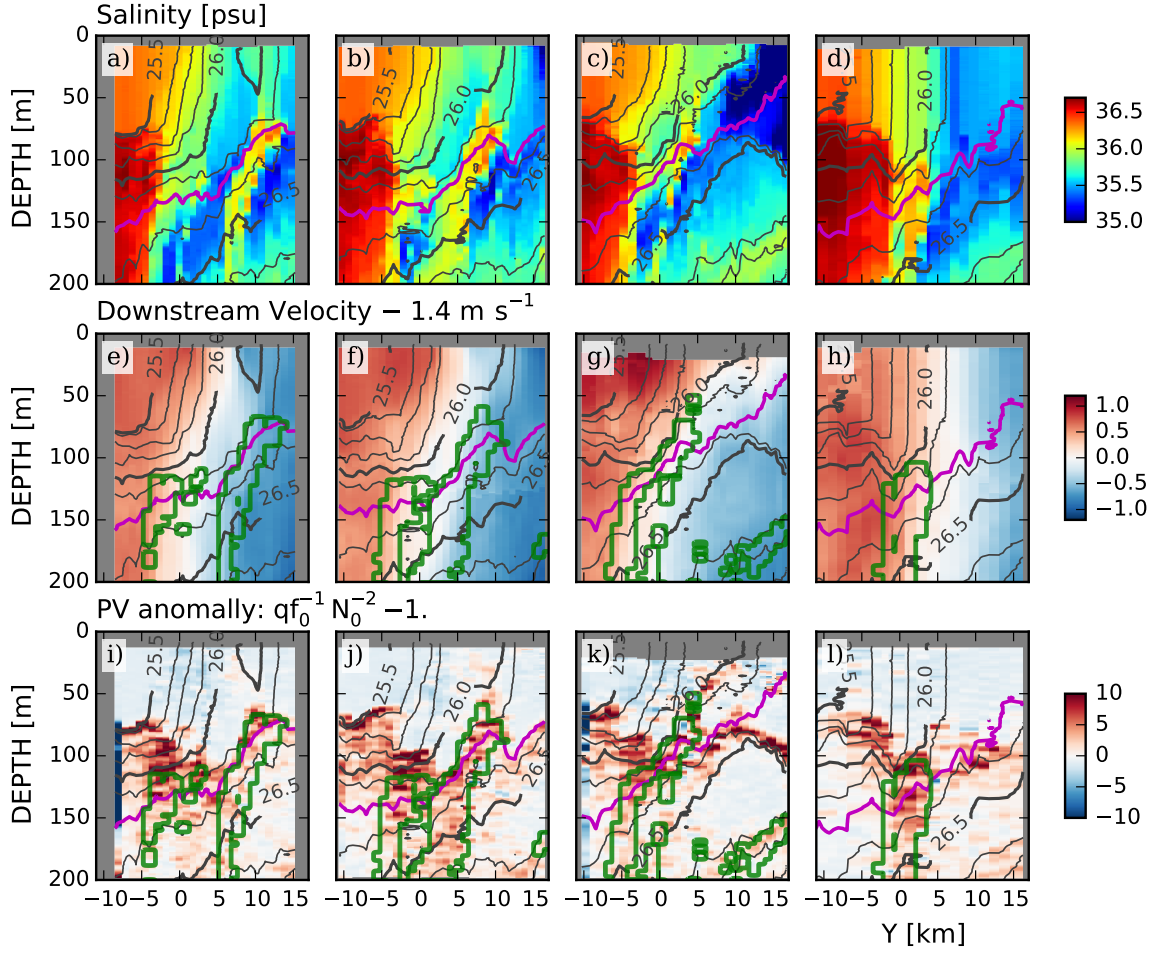

Figure 2: Cross sections of data collected across the Gulf Stream. Y is the cross-stream distance perpendicular to the path of the float, positive being northwards. The four columns correspond to the four sections labeled a-d in figure 1. Potential density is contoured in black and $\sigma_\theta = 26.25$ kg m^{-3} is magenta. Section a) is the furthest upstream section (65 W) and d) is the furthest downstream (63.75 W, figure 1). e)–h) downstream velocity calculated relative to the float's trajectory by removing the float's mean speed of $u_{float} = 1.4$ m s^{-1} for the observation period. Green contours are regions in temperature-salinity space labeled "streamers" in figure 3. i)–l) Potential vorticity anomaly.
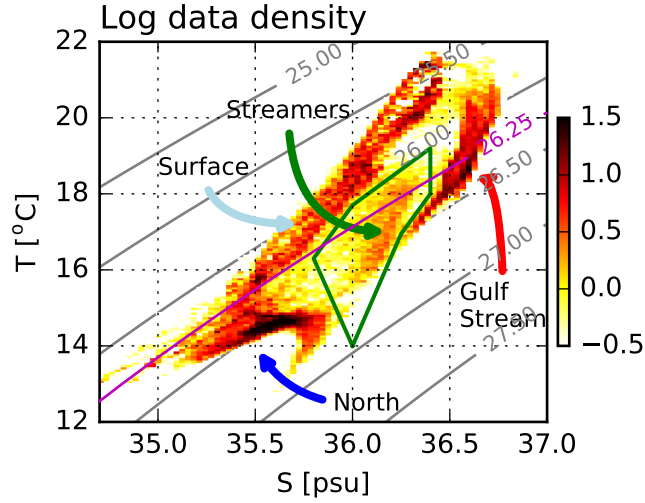

Figure 3: Logarithmically scaled histogram of 1-m by 1-km data points in temperature-salinity space (colours) of all the measurements in the occupation of the Gulf Stream. Between $\sigma_\theta = 26.1$ and $\sigma_\theta = 26.5 \text{kg m}^{-3}$ there is a class of water distinct from the salty GS water and the fresh water to the north, that we label "streamers" and delineate with a green box in T/S space. This water is contoured in green in figure 2e–l.
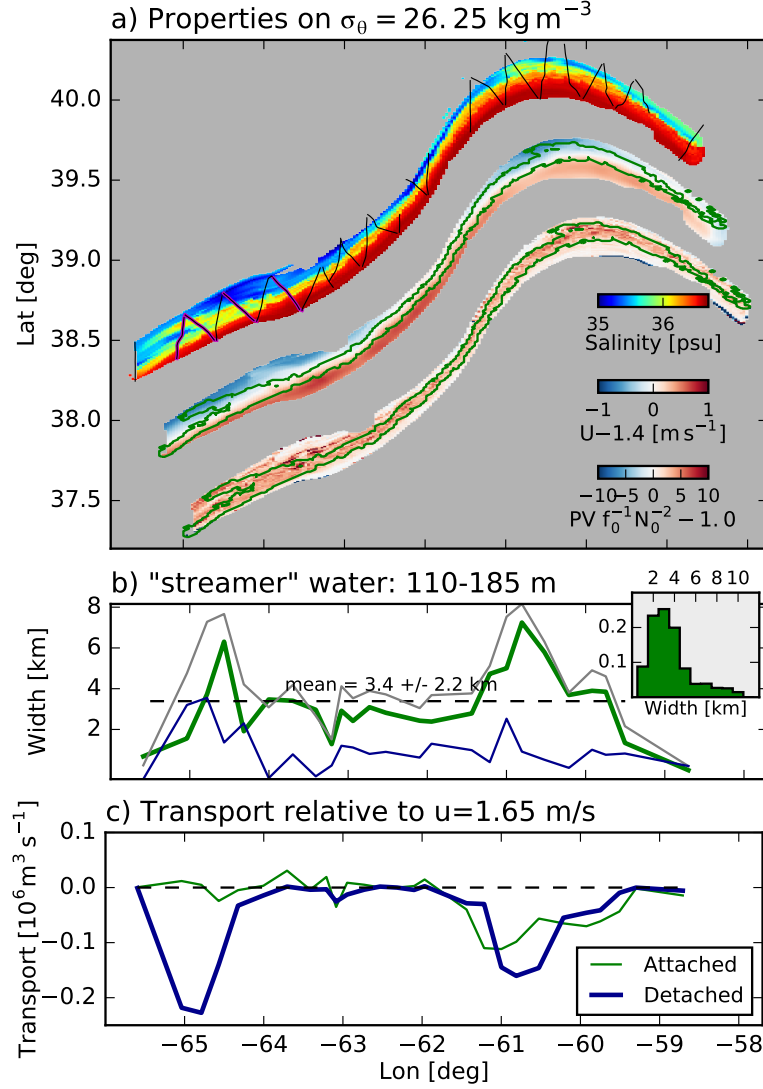

Figure 4: a) Interpolation of salinity, velocity, and potential vorticity anomaly onto the $\sigma_\theta = 26.25 \, \mathrm{kg \, m^{-3}}$ isopycnal, plotted geographically (with a small exaggeration of scale in the north-south direction, and the latter two fields offset slightly to the south-east). The ship track for the *Atlantis* is plotted in black, and the four cross-sections in figure 2 are plotted in magenta. The streamer water is contoured in green. b) Width of the streamer water averaged between 110 and 185 m, attached to the GS (green line), detached (blue line), and total (grey line); a water parcel is considered "attached" if there there is no more than one kilometer of water from the fresher water class to the north. c) Transport of the streamer water relative to $u = 1.65 \, \mathrm{m \, s^{-1}}$ (blue), chosen to make the transport of the water attached to the GS (green) approximately zero.
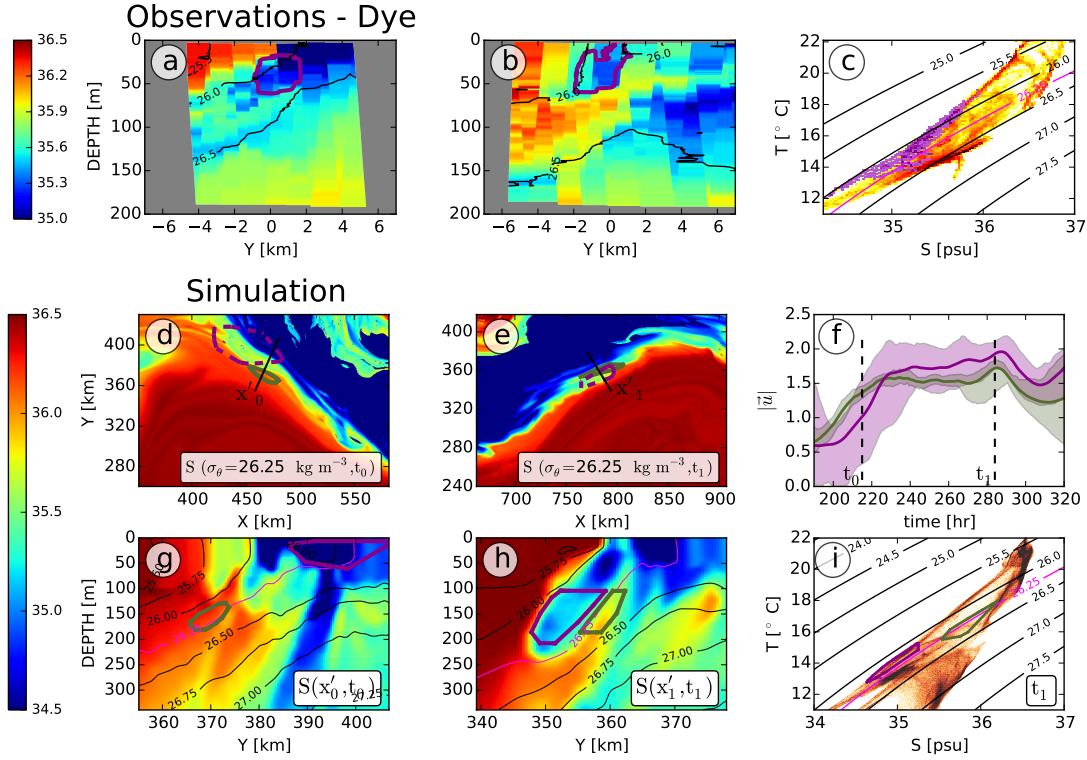

Figure 5: Evidence for entrainment of intrusions from a dye release and numerical simulation. a) Salinity section from an occupation of the GS 14 March. The location of a dye is contoured in magenta. b) Salinity section from downstream. A streamer has enfolded the dye in cold-fresh water between itself and the GS. c) Temperature-salinity diagram for this occupation. The temperature-salinity for the dye is coloured in dark magenta. d) Salinity in the GS on the $\sigma_\theta = 26.25$ kg m^{-3} isopycnal from a high-resolution numerical simulation at t_0. The green contours delineate the location of particles seeded downstream in the streamer at time $t_1 = t_0 + 70$h (see panels e and h) and advected *backwards* in time to t_0 showing where the streamer water originated. The dark magenta contour is the location of particles seeded in the fresh intrusion. The straight line shows the location of the salinity cross-section in panel g. e) as panel d, except at $t_1 = t_0 + 70$ h; this is the time and locations where the two clouds of particles were seeded. g) and h) salinity cross sections for times t_0 and t_1. The location of the particles is shown in green and dark magenta contours. The the $\sigma_\theta = 26.25$ kg m^{-3} isopycnal is contoured in light magenta. These panels show that the origin of the streamer water was in the GS front, and that the fresh-cold water (magenta contour) enfolded against the front came from north of the front. f) shows the speeds (min/max is shaded, and mean is the line) of the particle clouds in time, and shows that the intrusion water (magenta) accelerates relative to the streamer water (green). i) The temperature-salinity of all the data at t_1, with the clouds of seeded particles indicated in T/S space. Note that the green streamer water occupies a mixed mode between the warm GS waters and the cold and fresh water to the north.
